Reliable Computing I

Lecture 6: Information Redundancy

Instructor: Mehdi Tahoori

INSTITUTE OF COMPUTER ENGINEERING (ITEC) – CHAIR FOR DEPENDABLE NANO COMPUTING (CDNC)

KIT – University of the State of Baden-Wuerttemberg and
National Research Center of the Helmholtz Association

www.kit.edu

Today's Lecture

- Code, codeword, binary code
- Error detecting and correcting codes
- Hamming distance and codes
- Parity prediction
 - Odd/even parity
 - Basic parity approaches

(c) 2016, Mehdi Tahoori

Reliable Computing I: Lecture 6

2

Error Detection through Encoding

- At logic level, codes provide means of masking or detecting errors
- Formally, code is a subset S of universe U of possible vectors
- A noncode word is a vector in set $U-S$

X_1 is a codeword
<10010011>
due to multiple bit error,
becomes
 $X_3 = <10011100>$
not detectable

X_2 is a codeword,
becomes X_4 noncode
detectable

Basic Idea

- Start with k -bit data word
- Add r check bits
- Total = n -bit **codeword** ($n=k+r$)
- Map 2^k data words to 2^n sized codeword space
- Overhead = r/n (sometimes computed as r/k)
 - E.g., for (single-bit) parity, the overhead is $1/n$

Basic Concepts

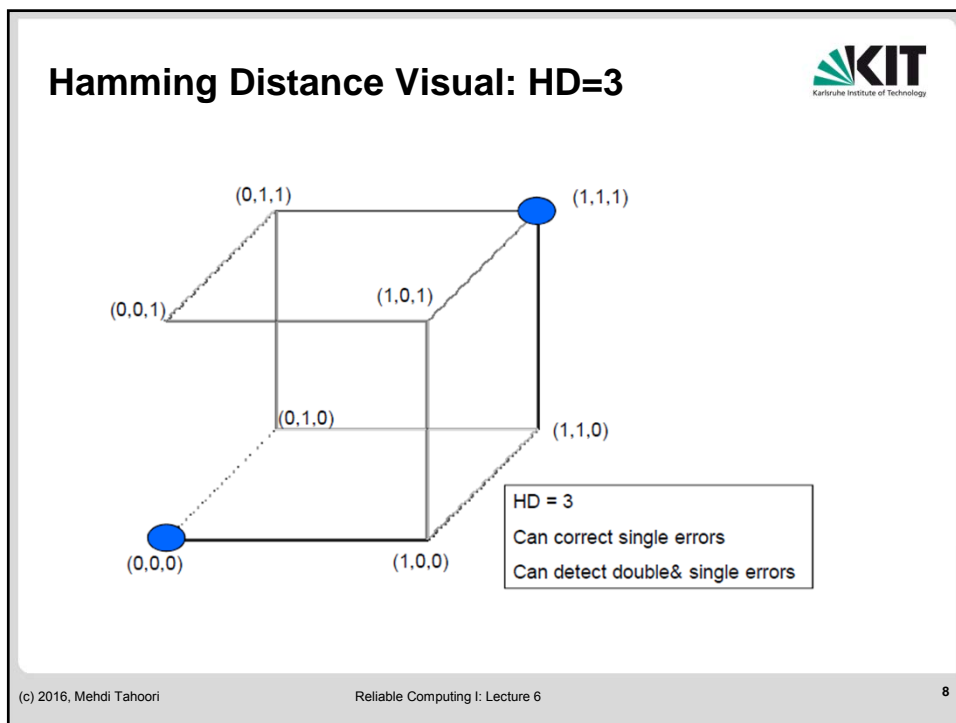

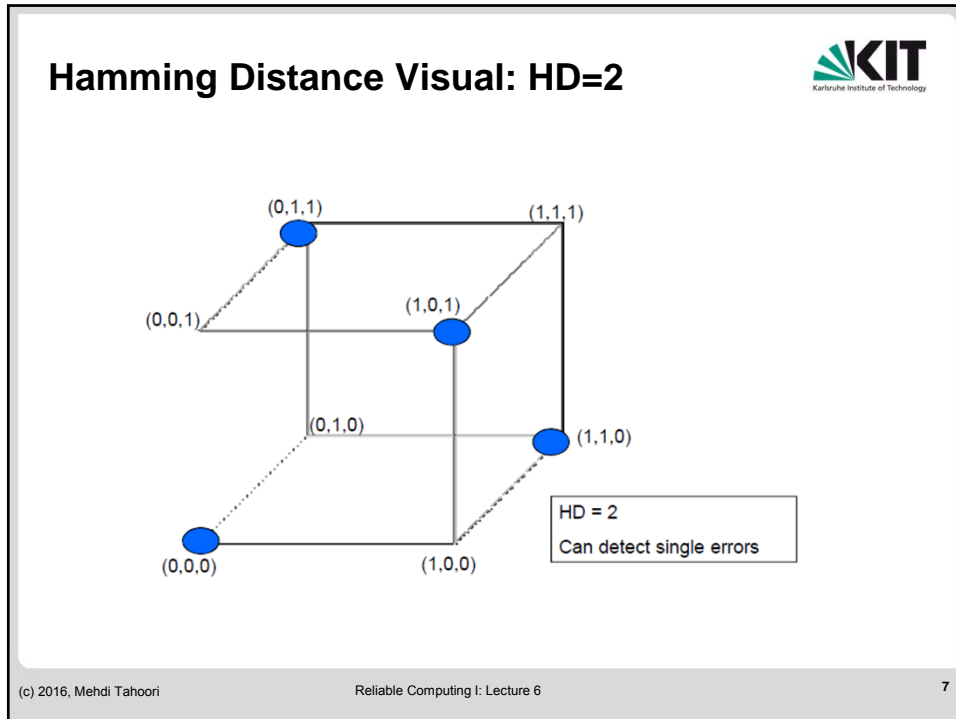

- Code, codeword, encoding, decoding error detection code, error correcting code
- Hamming distance properties:
 - The **Hamming weight** of a vector x (e.g., codeword), $w(x)$, is number of nonzero elements of x .
 - **Hamming distance** between two vectors x and y , $d(x,y)$ is number of bits in which they differ.
 - **Distance of a code** is a minimum of Hamming distances between all pairs of code words.
 - Example: $x = (1011)$, $y = (0110)$
 $w(x) = 3$, $w(y) = 2$, $d(x, y) = 3$

Hamming Distance

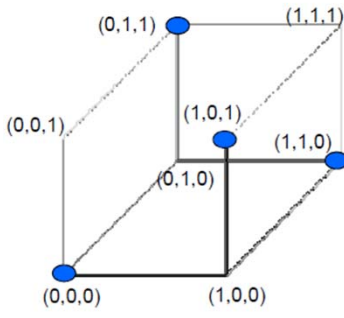

- Hamming distance (HD): number of bits in which two words differ from each other
 - E.g., 0010 and 1110 have a Hamming distance of ??
- For a group of codewords, the minimum HD between any two codewords determines the code's ability to detect and/or correct errors
 - This is a fundamental rule, not just some ad-hoc reasoning

Hamming Distance and Error Detection

■ Can detect up to t -bit errors if $HD \geq t + 1$

HD=2, detects 1-bit errors

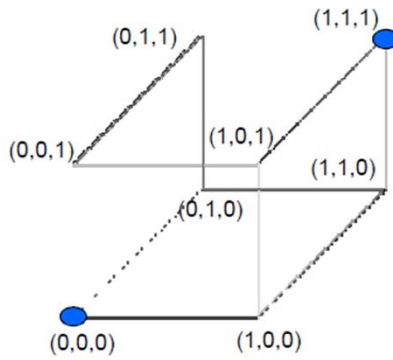

- What if we receive **111**?
 - Could've been **011**
 - Could've been **101**
 - Could've been **110**
 - What about **001**? Or **000**??
- What if we receive **011**?
 - Could it have been **001**???

(c) 2016, Mehdi Tahoori
Reliable Computing I: Lecture 6
9

Hamming Distance and Error Detection

■ Can detect up to t -bit errors if $HD \geq t + 1$

HD=3, detects 1,2-bit errors

(c) 2016, Mehdi Tahoori
Reliable Computing I: Lecture 6
10

Hamming Distance and Error Correction

- Can correct up to t -bit errors if $HD \geq 2t+1$

(c) 2016, Mehdi Tahoori

Reliable Computing I: Lecture 6

11

Hamming Distance and Error Correction

- Can correct up to t -bit errors if $HD \geq 2t+1$

- What if we receive **011**?
 - More likely to have been **111**
 - But could've been **000**
 - Guess that it was **111**
- What if we receive **111**?
 - Could it have been **000**?

(c) 2016, Mehdi Tahoori

Reliable Computing I: Lecture 6

12

Summary: Hamming Distance Properties

- To **detect** all error patterns of Hamming distance $\leq d$,
code distance must be $\geq d+1$
 - e.g., code with distance 2 can detect patterns with distance 1 (i.e., single bit errors)
- To **correct** all error patterns of Hamming distance $\leq c$,
code distance must be $\geq 2c + 1$
- To correct all patterns of Hamming distance c and detect up to d additional errors ,
code distance must be $\geq 2c + d + 1$
 - e.g., code with distance 3 can detect and correct all single-bit errors

Single-bit Parity

- Simplest error detection code
 - Adds one bit of redundancy to each data word
- Even (odd) parity: add bit such that total number of ones in codeword is even (odd)
 - E.g., 001010 gets a parity bit of 0 for even parity (1 for odd)
- Can detect all single-bit errors
 - Hamming distance ≥ 2
 - Could be greater than 2 if data words don't use all bit combinations
- Drawbacks:
 - Can't detect anything except single-bit errors

Parity Codes - Example

Odd and even parity codes for BCD data

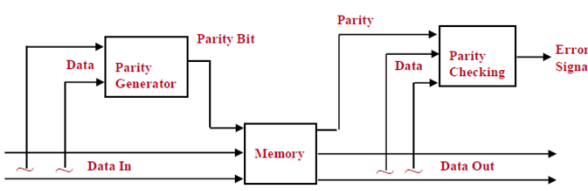

| Decimal Digit | BCD | BCD odd parity | BCD even parity |
|---------------|------|----------------|-----------------|
| 0 | 0000 | 00001 | 00000 |
| 1 | 0001 | 00010 | 00011 |
| 2 | 0010 | 00100 | 00101 |
| 3 | 0011 | 00111 | 00110 |
| 4 | 0100 | 01000 | 01001 |
| 5 | 0101 | 01011 | 01010 |
| 6 | 0110 | 01101 | 01100 |
| 7 | 0111 | 01110 | 01111 |
| 8 | 1000 | 10000 | 10001 |
| 9 | 1001 | 10011 | 10010 |

↑

Parity Bit

↑

Parity Bit

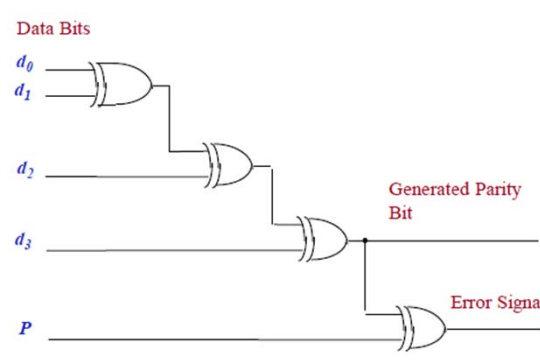

Organization of a memory that uses single-bit parity.
The parity bit is generated when data is written to memory and checked when data is read.

Parity Codes for Memory - Comparison

| Parity Code | Advantages | Disadvantages |
|--|--|--|
| Bit-per-word: one parity bit per data word | Detects all single-bit errors | Certain errors undetected, e.g., a word, including parity bit becomes all 1s, due to a failure of a bus or a set of data buffers. |
| Bit-per-byte: each data portion (e.g., a byte) is protected by a separate parity bit; the parity of one group should be even and the parity of the other group should be odd | Detects all-1s and all-0s conditions | Ineffective for multiple errors, e.g., the whole-chip failure |
| Bit-per-multiple-chips: one bit from each chip is associated with a single parity bit | Detects failure of entire chip | Cannot locate failure of complete chip |
| Bit-per-chip: each parity bit is associated with one chip of the memory | Detects single-bit errors and identifies chip with erroneous bit | Susceptible to whole-chip failure, i.e., a single chip error can result in multiple bits to be corrupted and this may go undetected. |
| Interlaced: similar to the bit-per-multiple-chips; must ensure that no two adjacent bits are from the same parity group | Detects errors in adjacent bits | Parity groups are not based on physical organization of the memory |

(c) 2016, Mehdi Tahoori Reliable Computing I: Lecture 6 18

Parity Prediction in Arithmetic Circuits

Binary Adder

- Two inputs: $a = (a_{n-1} \dots a_0 a_c)$ and $b = (b_{n-1} \dots b_0 b_c)$
- Two operands to be added: $(a_{n-1} \dots a_0)$ and $(b_{n-1} \dots b_0)$
- a_c and b_c are check bits of a and b respectively
- Encoded output will be $s = (s_{n-1} \dots s_0 s_c)$ where $(s_{n-1} \dots s_0)$ are determined by the ordinary binary addition of $(a_{n-1} \dots a_0)$ to $(b_{n-1} \dots b_0)$ and s_c is the check bit for $(s_{n-1} \dots s_0)$

- Then
$$s_c = \sum_{i=0}^{n-1} s_i = \sum_{i=0}^{n-1} a_i \oplus \sum_{i=0}^{n-1} b_i \oplus \sum_{i=0}^{n-1} c_i$$

- Reduces to
$$s_c = a_c \oplus b_c \oplus \sum_{i=0}^{n-1} c_i$$

Parity Prediction in Binary Adder

Binary Multiplier

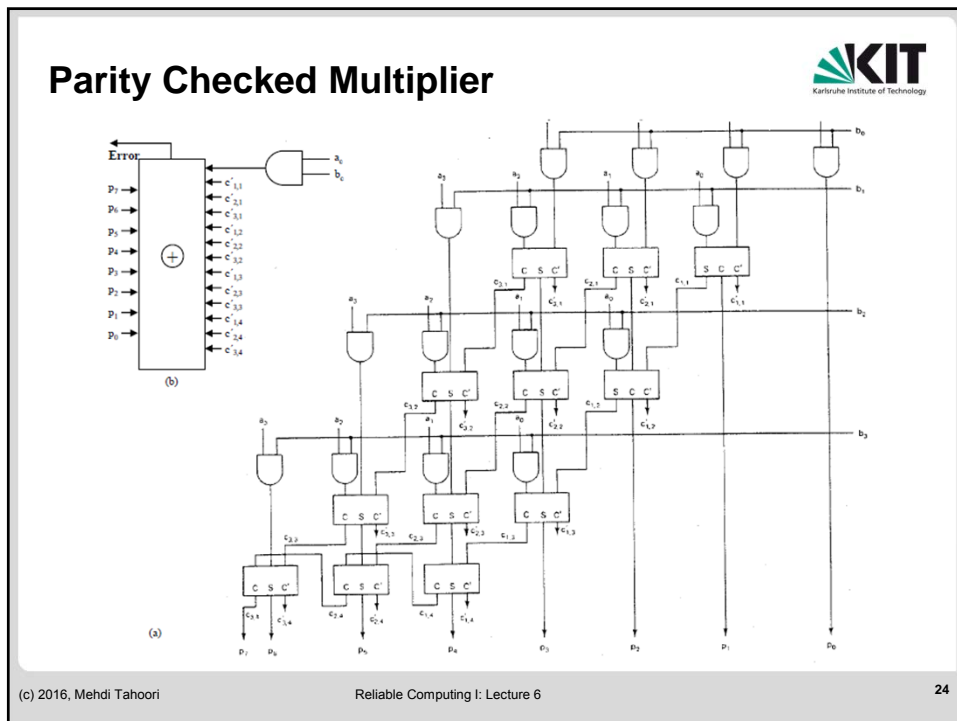

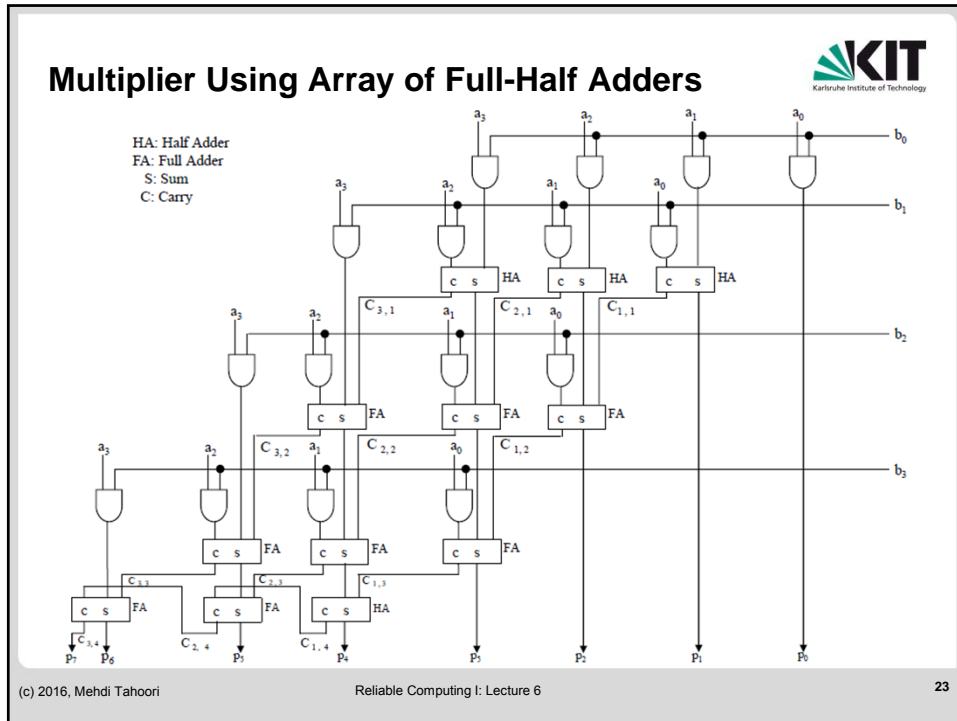

$$\begin{aligned}
 p_0 &= a_0 b_0 \\
 p_1 &= a_0 b_1 \oplus a_1 b_0 \\
 p_2 &= a_0 b_2 \oplus a_1 b_1 \oplus a_2 b_0 \oplus c_{1,1} \\
 p_3 &= a_0 b_3 \oplus a_1 b_2 \oplus a_2 b_1 \oplus a_3 b_0 \oplus c_{2,1} \oplus c_{1,2} \\
 p_4 &= a_1 b_3 \oplus a_2 b_2 \oplus a_3 b_1 \oplus c_{3,1} \oplus c_{2,2} \oplus c_{1,3} \\
 p_5 &= a_2 b_3 \oplus a_3 b_2 \oplus c_{3,2} \oplus c_{2,3} \oplus c_{1,4} \\
 p_6 &= a_3 b_3 \oplus c_{3,3} \oplus c_{2,4} \\
 p_7 &= c_{3,4}
 \end{aligned}$$

■ Therefore, denoting the check bit for $(p_7 \dots p_0)$ by p_c

$$\begin{aligned}
 p_c &= \sum_{i=0}^7 p_i \\
 &= \left(\sum_{i=0}^3 a_i \right) \left(\sum_{i=0}^3 b_i \right) \oplus \sum_{i=1}^3 \sum_{j=1}^4 c_{i,j} \\
 &= a_c b_c \oplus \sum_{i=1}^3 \sum_{j=1}^4 c_{i,j}
 \end{aligned}$$

(c) 2016, Mehdi Tahoori Reliable Computing I: Lecture 6 22

Overlapping Parity (for single-bit errors)

- Parity groups are formed with each bit appearing in more than one parity group
- Errors can be detected and located
- Erroneous bit can be corrected by a simple complementation

| Which bit has error? | Parity bits affected |
|----------------------|----------------------|
| i3 | p2, p1, p0 |
| i2 | p2, p1 |
| i1 | p2, p0 |
| i0 | p1, p0 |
| p2 | p2 |
| p1 | p1 |
| p0 | p0 |

When receiving codeword, re-compute 3 parity bits and compare to those that were sent. If different, can diagnose error (and correct it)!

Error Correction with Overlapped Parity

Generalized Overlapping Parity Codes

- The previous slide showed how to use overlapping parity to detect and diagnose single-bit errors
- For single-bit errors, there are $k+r$ possible errors
 - Therefore, we need $2^r \geq k + r + 1$ to uniquely diagnose errors
- In general, can extend this scheme to detect and diagnose more than single-bit errors
 - General approach called “Hamming Codes”

Hamming Error-Correcting Code

- Require from 10% to 40% redundancy
- Best thought of as overlapping parity
- The Hamming single-error correcting code uses c parity check bits to protect k bits of information:
 - $2^c \geq c + k + 1$
- Example:
 - suppose four information bits (d_3, d_2, d_1, d_0) and as a result three parity bits (p_1, p_2, p_3)
 - the bits are partitioned into groups as (d_3, d_1, d_0, p_1), (d_3, d_2, d_0, p_2) and (d_3, d_2, d_1, p_3)
 - the grouping of bits can be determine from a list of binary numbers from 0 to $2^k - 1$.
 - each check bit is specified to set the parity, either even or odd, of its respective group

Hamming Error-Correcting Code

**Determining the bit groups
(three parity bits)**

| | | | |
|-------|---|---|---|
| 0 0 0 | | | |
| 0 0 1 | 1 | | |
| 0 1 0 | | 2 | |
| 0 1 1 | 3 | 3 | |
| 1 0 0 | | | 4 |
| 1 0 1 | 5 | | 5 |
| 1 1 0 | | 6 | 6 |
| 1 1 1 | 7 | 7 | 7 |

Parity bits calculation

p1 = XOR of bits (3, 5, 7)
p2 = XOR of bits (3, 6, 7)
p3 = XOR of bits (5, 6, 7)

Parity checking

c1 = XOR of bits (1, 3, 5, 7)
c2 = XOR of bits (2, 3, 6, 7)
c3 = XOR of bits (4, 5, 6, 7)

- Observe that each group of bits for parity checking starts with a number that is a power of 2, e.g., 1, 2, 4.

(c) 2016, Mehdi Tahoori
Reliable Computing I: Lecture 6
29

(7,4) Hamming Code

- Class of (n,k) Hamming codes, e.g., (7,4) [r= n-k =3]
- Let i1, i2, i3, i4 be the information bits
- Let p1, p2, p4 be the check bits
- $p1 = i1 \text{ xor } i2 \text{ xor } i4$
- $p2 = i1 \text{ xor } i3 \text{ xor } i4$
- $p4 = i2 \text{ xor } i3 \text{ xor } i4$
- Let \underline{H} be the **Parity Check Matrix**
- If \underline{C} is a codeword, then $\underline{H} \underline{C} = \underline{0}$ (mult modulo 2!)
- Else, $\underline{H} \underline{C} = \underline{S}$, where \underline{S} is the **syndrome**
 - Syndrome identifies where error occurred (i.e., which bit)
 - This works out like magic because of some cute math

(c) 2016, Mehdi Tahoori
Reliable Computing I: Lecture 6
30

(7,4) Hamming Code

■ $\underline{H} =$

| p1 | p2 | i1 | p4 | i2 | i3 | i4 |
|----|----|----|----|----|----|----|
| 1 | 0 | 1 | 0 | 1 | 0 | 1 |
| 0 | 1 | 1 | 0 | 0 | 1 | 1 |
| 0 | 0 | 0 | 1 | 1 | 1 | 1 |

■ Info word: 0101: $p_1 = 0$, $p_2 = 1$, $p_4 = 0$

■ codeword is 0100101

■ Example 1:

■ received error-free codeword $R = 0100101$

■ Compute syndrome: $\underline{S} = \underline{H} R = \underline{0} = [0\ 0\ 0]$

■ Example 2:

■ received $R = 0110101$ (i.e., error in bit position 3)

■ Compute syndrome: $S = H R = [1\ 1\ 0]$

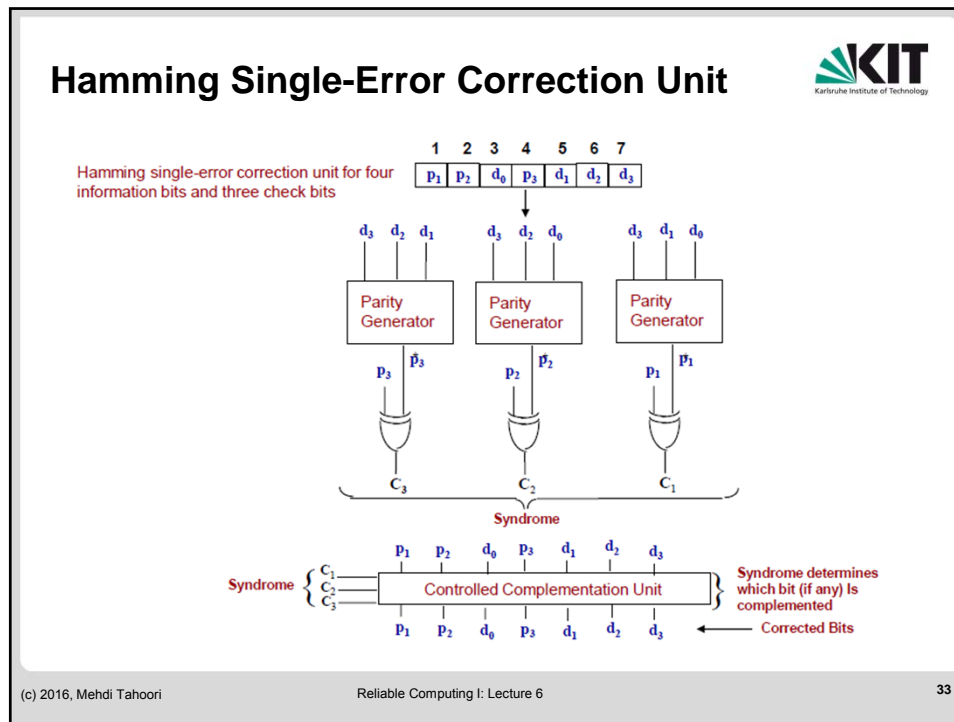

■ Read backwards this is $011 = 3$

Check Bits and Syndromes for Single-Bit Errors

- The original data is encoded by generating a set C_g , of parity bits.
- To check correctness, the encoding process is repeated and a set C_c , of parity bits is generated.
- If C_g and C_c agree, the information is correct.
- If C_g and C_c disagree, the information is incorrect and must be corrected.
- To aid the correction, a *syndrome* is defined:
 - The syndrome is a binary word that has 1 in each bit position in which C_g and C_c disagree; the syndrome points directly to the erroneous bit.

| Erroneous bits | Check bits affected | Syndromes |
|----------------|---------------------|-----------|
| d_0 | p_1, p_2 | 110 |
| d_1 | p_1, p_3 | 101 |
| d_2 | p_2, p_3 | 011 |
| d_3 | p_1, p_2, p_3 | 111 |
| p_1 | p_1 | 100 |
| p_2 | p_2 | 010 |
| p_3 | p_3 | 001 |

Single Error Correction and Double Error Detection Hamming Code (SEC-DED)

| | p ₁ | p ₂ | d ₀ | p ₃ | d ₁ | d ₂ | d ₃ | p ₄ |
|--|----------------|----------------|----------------|----------------|----------------|----------------|----------------|----------------|
| | 1 | 1 | 1 | 1 | 1 | 1 | 1 | 1 |
| | 1 | 0 | 1 | 0 | 1 | 0 | 1 | 0 |
| | 0 | 1 | 1 | 0 | 0 | 1 | 1 | 0 |
| | 0 | 0 | 0 | 1 | 1 | 1 | 1 | 0 |

| c ₁ | c ₂ | c ₃ | c ₄ | |
|----------------|----------------|----------------|----------------|--|
| 0 | 0 | 0 | 0 | No errors |
| x ₃ | x ₂ | x ₁ | 1 | Single error in a position (x ₁ x ₂ x ₃) |
| y ₃ | y ₂ | y ₁ | 0 | Double error |
| 0 | 0 | 0 | 1 | Error in bit p ₄ |

- Consider a data word consisting of four information bits
- Three parity bits are needed to provide single error correction
- Adding an extra parity bit, the Hamming code can be used to **correct single bit errors and to detect double errors**

Check bits computation

P₁ = XOR (3, 5, 7)
P₂ = XOR (3, 6, 7)
P₃ = XOR (5, 6, 7)
P₄ = parity over the first 7 bits of the code word

Syndromes computation

C₁ = XOR (1, 3, 5, 7)
C₂ = XOR (2, 3, 6, 7)
C₃ = XOR (4, 5, 6, 7)
C₄ = parity over all 8 bits of the code word

(c) 2016, Mehdi Tahoori Reliable Computing I: Lecture 6 34

Single Error Correction and Double Error Detection Hamming Code (SEC-DED) Example

| | p_1 | p_2 | d_0 | p_3 | d_1 | d_2 | d_3 | p_4 |
|---|-------|-------|-------|-------|-------|-------|-------|-------|
| 1 | 1 | 1 | 0 | 0 | 1 | 1 | 0 | 0 |
| 2 | 1 | 1 | 1 | 0 | 1 | 1 | 0 | 0 |
| 3 | 1 | 1 | 0 | 0 | 1 | 0 | 0 | 0 |
| 4 | 0 | 1 | 0 | 0 | 0 | 1 | 0 | 0 |
| 5 | 1 | 1 | 0 | 0 | 1 | 1 | 0 | 1 |

Initial daa
 $d_0 d_1 d_2 d_3$
0 1 1 0

Failure scenarios

| | c_1 | c_2 | c_3 | c_4 |
|---|-------|-------|-------|-------|
| 1 | 0 | 0 | 0 | 0 |
| 2 | 1 | 1 | 0 | 1 |
| 3 | 0 | 1 | 1 | 1 |
| 4 | 0 | 0 | 1 | 0 |
| 5 | 0 | 0 | 0 | 1 |

Corresponding Syndromes

- No errors
- Single error in position 3
- Single error in position 6
- Double error
- Error in bit p_4
